Abstract

Objective: Despite widespread use of proton pump inhibitors (PPIs), the incidence of esophageal adenocarcinoma (EAC) continues to rise. PPIs reduce reflux acidity, but only transiently inactivate gastric enzymes. Nonacid reflux, specifically nonacid pepsin, contributes to carcinogenesis in the larynx. Given the carcinogenic potential of pepsin and inefficacy of PPIs to prevent EAC, the presence and effect of pepsin in the esophagus should be investigated.

Methods: Normal and Barrett’s biopsies from 8 Barrett’s esophagus patients were collected for pepsin analysis via Western blot and reverse transcriptase-polymerase chain reaction (RT-PCR). Human esophageal cells cultured from healthy patients were treated with pepsin (0.01-1 mg/mL; 1-20 hours), acid (pH 4) ± pepsin (5 minutes); real-time RT-PCR, ELISA, and cell migration were assayed.

Results: Pepsin was detected in all 8 Barrett’s and 4 of 8 adjacent normal specimens. Pepsinogen mRNA was observed in 22 Barrett’s, but not in normal adjacent samples. Pepsin induced PTSG2 (COX-2) and IL-1β expression and cell migration in vitro.

Conclusions: Pepsin is synthesized by metaplastic, Barrett’s esophageal mucosa. Nonacid pepsin increases metrics of tumorigenicity in esophageal epithelial cells in vitro. These findings implicate refluxed and locally synthesized pepsin in development and progression of EAC and, in part, explain the inefficacy of PPIs in the prevention of EAC.

Keywords

Introduction

Esophageal adenocarcinoma (EAC) boasts the fastest rising incidence of any cancer in the United States.1 With an average 5-year survival rate of only 17%, it ranks seventh among all cancers in mortality and is one of few cancers contributing to increasing death rates among males in the United States.2 The mortality of EAC is attributed not only to its aggressive nature but also to failed screening indicators. Patient selection for endoscopic screening is currently based on severity of classical gastroesophageal reflux disease (GERD) symptoms (eg, heartburn, regurgitation, or dysphagia). These criteria succeed in identifying only 5% of EAC patients.3 Widespread use of proton pump inhibitors (PPIs), which provide symptom relief without reducing reflux of other noxious gastric contents, may be responsible for the disparity between symptom severity and EAC. This class of antisecretory therapy is the third highest selling drug category in the United States, accounting for more than 113 million prescriptions annually, including many prescriptions for infants, and sales exceeding $14 billion. Up to 70% of PPI use is for unapproved indications, and patients often continue therapy for extended durations without an end point.4-6 Yet, rather than having an advantageous effect on EAC, ever-growing PPI use is associated with a
parallel rise in EAC incidence—an increase of more than 460% since the 1970s when acid suppression medication became the world’s first billion dollar drug.\(^7\)

In a recent study, endoscopic examination of 769 patients with GERD or laryngopharyngeal reflux revealed a positive correlation between PPI use and increased odds for the presence of esophageal adenocarcinogenesis.\(^8\) Furthermore, study subjects taking PPIs were more likely to have esophageal adenocarcinogenesis if they reported mild to no symptoms. A study of 9883 patients in Denmark similarly found that high adherence and long-term use of PPIs was associated with significantly increased risk of adenocarcinoma or high-grade dysplasia.\(^9\) Antireflux surgery, however, which impedes reflux of all gastric contents, was associated with regression of Barrett esophagus and/or dysplasia.\(^10\) These findings not only highlight the potential danger of symptom masking by PPIs but also suggest that nonacid components of refluxate could be primarily responsible for EAC progression. Bile salts and enzymes have been shown to be more injurious to esophageal mucosal surfaces in the higher pH refluxate characteristic of patients on PPIs,\(^11,12\) and non-acid pepsin has been shown to promote tumorigenesis in models of weak or non-acid reflux that afflicts the upper airways.\(^13-17\) The role of pepsin, independent of acid, in EAC development and progression is relatively unknown.

Here we aim to investigate the presence of esophageal pepsin in patients with the reflux-attributed metaplastic condition, Barrett’s esophagus (BE), and examine the potential of pepsin to drive inflammatory and carcinogenic changes in esophageal epithelial cells in vitro.

**Methods**

**Human Biopsy Specimens**

For pepsin and pepsinogen analysis, intraoperative pinch biopsy specimens (1-2 mm\(^3\)) were obtained through upper endoscopy during elective general surgery procedures (gastric bypass, sleeve gastrectomy, incisional hernia, Nissen fundoplication) from patients with a previous histological diagnosis of BE; Medical College of Wisconsin (MCW) Institutional Review Board (IRB) PRO00006838. Biopsies were obtained from BE and neighboring normal tissue. BE and normal specimens were visually identified by the operating physician. Patients previously diagnosed with BE who underwent ablation and subsequently tested BE negative were excluded.

For cell culture, intraoperative pinch biopsy specimens (1-2 mm\(^3\)) were harvested from the esophagus of patients with no prior history or preoperative symptoms of reflux (GERD-Health Related Quality of Life survey score of 0), and no indication of esophageal malignancy, undergoing surgery for elective general surgery procedures; MCW IRB PRO00004777.

Specimens were placed in saline for transport to the laboratory.

**Human Esophageal Epithelial Primary Cell Culture**

An in vitro cell culture model was created to facilitate investigation of cell and molecular inflammatory and carcinogenic changes following pepsin exposure. Esophageal epithelial (EE) cells were cultured from biopsy and epithelial phenotype confirmed as described previously.\(^18\) Cells of less than 5 passages were used for all experiments.

**SDS-PAGE/Western Blot**

Presence of pepsin and pepsinogen protein in BE and neighboring normal tissue was assayed via sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE)/Western Blot. Pepsin protein observed in biopsies lacking pepsinogen mRNA and protein could be presumed to be of gastric origin, that is, deposited during a reflux event. Pepsin observed in biopsies that contained pepsinogen mRNA and protein could be of local and/or gastric origin. Total protein was extracted from specimens as described\(^19\) and quantified by Protein Assay (BioRad, Hercules, CA, USA). Thirty micrograms of total protein was run by 10% SDS-PAGE alongside human pepsin 3b (positive control; from human gastric juice as described\(^20\); MCW IRB PRO00004759) and human pepsinogen I (negative control; Sigma-Aldrich, St Louis, MO, USA), transferred to PVDF membrane (GE Healthcare, Piscataway, NJ, USA) and probed with a mouse monoclonal antibody developed against residues 296 to 311 of human pepsinogen A (SwissProt P00790) by Promab (Richmond, CA, USA) with a limit of detection of 0.2 ng pepsin 3b and 100 ng pepsinogen I via SDS-PAGE/Western blot. Blots were incubated with peroxidase-conjugated secondary antibody (P0447/P0448, Dako, Copenhagen, Denmark) and Western Blotting Luminol Reagent (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and signal detected by X-ray film. All antibodies were diluted in phosphate buffered saline (PBS), 0.1% Tween-20, and 5% nonfat dry milk. Rabbit anti-pepsin antibody (sc-99081, Santa Cruz Biotechnology) with greater affinity for pepsinogen relative to pepsin was used for detection of pepsinogen protein.

**Pepsinogen Reverse Transcriptase-Polymerase Chain Reaction (RT-PCR)**

RNA was extracted from esophageal biopsies using TRIZOL (Life Technologies), cleaned, and DNase (RNeasy Mini Kit with DNase, Qiagen, Germantown, MD, USA). Reverse transcription was performed on 250 ng esophageal biopsy or gastric RNA (Agilent Technologies, Santa Clara, CA, USA)
using oligo d(T) primers (Superscript III Reverse
Transcription kit, Life Technologies). Pepsinogen A was
amplified (forward: ACCGTGGACAGCATCCATG;
reverse: TCTTCCCTGGAGGTGGCTG) with reaction
conditions of 5 minutes at 95°C, 30 cycles of: 30 seconds at
94°C, 30 seconds at 62°C, 30 seconds at 72°C, and 5 min-
utes at 72°C. Hypoxanthine-guanine phosphoribosyltrans-
ferase 1 (HPRT1) was amplified as a positive control
(forward: TGCTCGAGATGTGATGAGG; reverse:
CCTGACCAAGGAAGCACAAG) with the following dif-
culty in reaction conditions (35 cycles, 55°C annealing).
Primers spanned >100 bp introns. Amplicon was separated on
2% agarose alongside 50 to 1000 bp DNA Marker
(Cambrex, East Rutherford, NJ, USA).

Immunohistochemistry

Immunohistochemistry was used to confirm pepsin protein
presence in BE and absence in neighboring normal tissue.
Esophageal biopsies were fixed in formalin, paraffin-embed-
ded, sectioned to 4 µm and mounted to glass slides. Following
deparaffinizing, antigen retrieval was performed on PT Link
(Dako) at 97°C for 20 minutes. Immunohistochemistry with
mouse anti-pepsin antibody, peroxidase-conjugated second-
ary antibody (Dako), diaminobenzidine, and hematoxylin
was performed on the Autostainer Plus using the EnVision
FLEX High pH Detection Kit (Dako). Images were col-
lected on a Nikon Eclipse Ti using NIS Elements software
(Nikon, Tokyo, Japan).

IL-1β ELISA

IL-1β, a cytokine involved in chronic inflammation and
cancer, was assayed in pepsin-treated and control EE cells
to determine whether nonacid pepsin exposure could induce
the IL-1β cancer-related signaling pathway. EE cells were
grown to 75% confluence and treated in duplicate with por-
cine pepsin (0.01 mg/mL; Sigma-Aldrich) in normal growth
media for 1 or 20 hours, or normal growth media without
pepsin for 20 hours (control). Culture supernatants were
collected and assayed in duplicate using Human IL-1 beta/
IL-1F2 Quantikine ELISA Kit (R&D Systems, Minneapolis,
MN, USA). Student’s t test was used to determine statistical
significance.

PTGS2 (COX-2) Real-Time PCR

Gene expression of PTGS2, which is positively regulated by
IL-1β and associated with chronic inflammation, cancer, and
EAC prognosis, was assayed in pepsin and/or acid-treated
and control EE cells to determine whether nonacid pepsin
exposure could induce PTGS2 expression, potentially as a
result of activation of the IL1-β cancer-related signaling
pathway, and the degree to which it did relative to acid and
acidified pepsin. EE cells were grown to 75% confluence
and treated in 5 replicates with porcine pepsin (0.01 mg/mL)
in normal growth media (pH 7.4) for 1 or 20 hours, growth
media at pH 4 with or without porcine pepsin (0.01 mg/mL)
for 5 minutes, or normal growth media without pepsin for 20
hours (control). Cells were rinsed with PBS. RNA was har-
vested using TRIZOL. A total of 150 ng RNA was reverse
transcribed using Superscript VILO Synthesis Kit (Life
Technologies) and PCR performed using Taqman gene
expression assays (HPRT: Hs02800695_m1 and PTGS2
(COX-2); Hs00153133_m1) in a Viia7 real-time PCR instru-
ment (Life Technologies). Ct values >35 were used for anal-
ysis. Ct values were normalized to the housekeeper (HPRT1).
Replicated delta-Ct values within a plate were averaged.
Averaged values from all genes were analyzed jointly in a
mixed effects model with fixed group, gene, and group-by-
gene interaction effects and random plate and sample effects.
After finding a significant gene-by-group interaction (P <
.0001), slice F-tests were performed to compare groups
within each gene, followed by Tukey’s HSD adjusted pair-
wise comparisons. Analyses were performed using SAS 9.3
(SAS Institute, Cary, NC, USA).

Cell Migration Assay

The scratch, or wound-healing, assay is a commonly used
test of tumorigenicity, which assesses the rate of repopula-
tion of a cell-free area as a function of cell migration and prolif-
eration. To determine the effect of nonacid pepsin, relative to
acidified pepsin or acid, on wound healing as a measure of
cell migration and proliferation EE cells were grown to 100%
confluence on a 96-well Essen BioScience ImageLock Plate
(Essen Bioscience, Ann Arbor, MI, USA) at 37°C with 5%
CO2. In 12 technical replicates, cells were either untreated or
pretreated with growth media at pH 4 with or without porcine
pepsin (0.01 mg/mL) for 5 minutes, rinsed with PBS and
replaced in normal growth media. Consistent wounds were
made using a WoundMaker (Essen Bioscience). Wells were
rinsed with PBS and normal growth media or growth media
with porcine pepsin (0.1 or 1 mg/mL) was replaced for the
duration of the assay. The plate was placed in an IncuCyte
FLR incubator and live-cell imaging system (Essen
Bioscience) for data collection at 2-hour time intervals over
24 hours. Essen Bioscience software returned the Relative
Wound Density (RWD), corresponding to cell density within,
relative to outside, the wound area, and confluence corre-
sponding to the cell confluence across the well. RWD col-
lected over time was summarized for each well via the area
under the curve (AUC) calculated by the trapezoidal rule.
The AUC values were compared between groups using one-
way ANOVA; pairwise comparisons were adjusted using
Tukey’s method. Significance level was set to 5% (2-sided
comparisons). Analyses were performed using SAS 9.3 (SAS
Institute, Cary, NC, USA).
Results

Pepsin Detection in Barrett’s Esophagus Patient Specimens

SDS-PAGE/Western blot analysis of BE and neighboring normal specimens demonstrated that pepsin protein was present in all 8 Barrett’s specimens and in 4 of 8 adjacent normal specimens analyzed (Table 1 and representative image, Figure 1A). Pepsin protein presence in BE specimens, and absence in a neighboring normal sample, was also demonstrated by immunohistochemistry (Figure 2). Pepsinogen A mRNA was observed in 2 Barrett’s specimens but was not observed in normal adjacent samples (Figure 1B). Pepsinogen protein was observed in pepsinogen mRNA-positive specimens whereas little to no pepsinogen was detected in neighboring normal tissue (Figure 3).

In Vitro Analyses: IL-1β and PTGS2/COX-2 Expression and Cell Migration

Concentrations of IL-1β in cell culture supernatants of human esophageal primary cell cultures were 9.65 ± 1.26 pg/mL in control or untreated cells, 19.18 ± 0.62 pg/mL in cells treated with 0.1 mg/mL pepsin for 1 hour, and 20.43 ± 0.54 in cells treated with 0.1 mg/mL pepsin for 20 hours. Elevation in IL-1β was statistically significant \((P < .05); \text{Table 2})\. PTGS-2/COX-2 was elevated approximately 2-fold in all treatment conditions \((P < .05); \text{Table 2})\. RWD metric of cell migration demonstrated a linear increase for approximately the first 8 hours of observation in most conditions (Figure 4). Area under the curve analysis demonstrated that only 0.1 mg/mL pepsin treatment induced a significant increase in RWD (Tables 3 and 4). Pepsin treatment at 1 mg/mL produced no

change in RWD relative to control condition. Acid and combined acid and pepsin treatment significantly reduced RWD. Significant cell death was observed in acid and combined acid and pepsin treatment conditions (Tables 5 and Figure 5), whereas cells in other conditions appeared healthy throughout the assay duration.

**Discussion**

The role of pepsin is typically considered secondary to acid in the pathophysiology of GERD, as evidenced by the exclusively acid-focused treatment paradigm of the past 4 decades. However, in the context of weak or nonacid reflux that afflicts the proximal airways, nonacid pepsin has been shown to activate inflammatory and carcinogenic signaling pathways, promote hyperproliferation, cell migration and anchorage-independent growth, and increase tumor volume in a hamster buccal pouch model. Although the exact mechanism by which refluxed nonacid pepsin elicits such adverse effects is unknown, it has been shown that in a nonacid environment, pepsin’s enzymatic activity is neutralized allowing for interaction with a cell surface receptor, uptake via receptor-mediated endocytosis, and storage for up to 12 hours in intracellular vesicles that become increasingly acidic, generating conditions that would restore its proteolytic activity. Acid suppression pharmacotherapy does not reduce the frequency or number of reflux events, merely the acidity of such events; therefore, the exposure of the esophagus to nonacid components of refluxate is not reduced in patients taking PPIs. In previous work, we have shown that esophageal epithelial cells exhibit receptor-mediated endocytosis and intracellular storage of pepsin when exposed in a pH neutral environment. We did not, however, investigate whether endocytosed pepsin in esophageal cells produced inflammatory and carcinogenic effects similar to that observed in upper airway cells and tissues.

In the study described herein, pepsin was observed in the esophageal mucosa of patients with the reflux-associated preneoplastic condition, Barrett’s epithelium. Protein and mRNA corresponding to the pepsin precursor, pepsinogen, was observed in some Barrett’s epithelium specimens as well, revealing potential local production in addition to deposition of gastric pepsin following a reflux event. Pepsinogen mRNA was not observed in any neighboring normal specimens. These results corroborate previous studies demonstrating the presence of chief cells and pepsinogen mRNA and protein production in BE and the absence of pepsin protein in esophageal biopsies of pH confirmed reflux-free control subjects. Although historically it was concluded that local pepsin synthesis in Barrett’s epithelium did not pose a significant risk in terms of disease progression, advances made in the field over the past decade regarding the contribution of nonacid pepsin to inflammation and carcinogenesis strongly suggest otherwise.

To investigate the mechanisms by which nonacid pepsin might elicit esophageal epithelial cell damage, a primary culture of human esophageal epithelial cells was treated with nonacid pepsin and metrics of inflammation and carcinogenesis were examined. In this study, IL-1β protein expression, PTGS2 (COX-2) gene expression, and cell migration were elevated in cells treated with pepsin. The proinflammatory cytokine, IL-1β, is consistently upregulated in BE and induces spontaneous carcinogenesis of the esophagus in a transgenic mouse model. PTGS2/COX-2, which is positively regulated by IL-1β, is a prognostic marker of EAC and candidate target for medical therapy. COX-2 inhibitors have been shown to abrogate cell proliferation in EAC cells in vitro, reduce tumor incidence in animal models of EAC, and slow Barrett’s epithelium cell proliferation in a clinical trial. Interestingly, an epidemiologic study demonstrated that long-term PPI therapy has no advantageous effect on COX-2 expression, suggesting that nonacid components of reflux may be responsible for continued dysregulation of COX-2 in patients taking PPIs.
In experiments described herein, PTGS2/COX-2 was elevated approximately 2-fold not only in cells treated with pepsin but also in cells treated with acid and combined acid and pepsin as well. In contrast, cell migration was enhanced by pepsin but impeded by brief exposure to acid or acid and pepsin. The difference in response...
may reflect the resting period of cells between acid treatment and assay: cells were harvested immediately post-treatment for PTGS2/COX-2 analysis whereas cell migration was measured starting 2 hours postexposure. A significant reduction in cell number (relative to control) was observed in the combined acid and pepsin treated condition as soon as 30 minutes following treatment, becoming more extreme and evident in acid-only treated cells by 24 hours posttreatment. In previous work, we have found that even brief acid or acid and pepsin treatment incurs cell death in airway epithelial cells in vitro (unpublished) whereas pepsin treatment results in hyperproliferation and promotion of markers of inflammation and carcinogenesis. While other authors have reported an antiproliferative effect of acid on Barrett’s cancer cells and on Barrett’s mucosal explants,35,36 this study is the first to show an antiproliferative effect of acid on normal esophageal cells. The implication of this finding, which is supported by the association of PPI use with EAC, is that nonacid reflux, and refluxed nonacid pepsin in particular, may present a greater threat of carcinogenesis than does acid.

Additional research is anticipated to address limitations of this study. First, BE specimens were identified as such only by visual inspection of the operating surgeon. Histochemical analysis of each biopsy by a qualified pathologist would be required to verify that the region used for molecular studies was indeed BE. Therefore, the absence of pepsinogen message in some BE specimens may be false negatives rather than an indication of differences between patients. Furthermore, given the small study size, no useful correlation could be drawn between clinical measures of disease and levels of pepsin/pepsinogen protein or mRNA. In future studies, a larger population will be recruited from whom data such as pathological grading, pH-manometry testing, and prognostic indicators will be obtained. As not all Barrett’s epithelium progresses to adenocarcinoma, such in-depth study should help determine the utility of phenotypic traits, such as local pepsin production, as prognostic indicators.

*Relative to control.

Conclusion

The rapid and concomitant rise of EAC with PPI usage over the past 40 years clearly illustrates the failure of the current acid-targeting treatment paradigm to prevent reflux-attributed carcinogenesis and implicates nonacid reflux in development and progression of EAC. The study described herein demonstrates the presence of pepsin of both gastric and local origin in preneoplastic human esophageal mucosa and the capacity of nonacid pepsin to alter markers of inflammation and carcinogenesis in esophageal cells in vitro. These data may, in part, explain the risk of EAC associated with long-term PPI use and lend support for the use of more comprehensive strategies for prevention of reflux-attributed disease.
